

Optocouplers and Optocoupler Switches

AI Overview

Optocouplers (or opto-isolators) transfer electrical signals between isolated circuits using light, and can function as switches to control current flow without direct electrical contact.

What is an Optocoupler?

An optocoupler is an electronic component that allows signal transfer between two electrically isolated circuits using light. It typically consists of a light-emitting diode (LED) on the input side and a photodetector (such as a phototransistor) on the output side, all housed in a single package. When the LED receives an electrical signal, it emits light, usually infrared, which is detected by the phototransistor. This causes the phototransistor to conduct, effectively reproducing the input signal on the output side while maintaining electrical isolation.

How Optocouplers Work as Switches

When used as a switch, the phototransistor in an optocoupler operates like a simple on/off device. If the LED is on, the phototransistor saturates and allows current to flow, acting as a closed switch. When the LED is off, the phototransistor stops conducting, acting as an open switch. Unlike standard transistors, the base of the phototransistor is usually left unconnected, so it switches consistently regardless of whether the load is connected to the collector or emitter, with only the output polarity changing. However, optocouplers are limited in output current, typically only a few tens of milliamperes, so they are not suitable for directly driving heavy loads like motors.
